Abstract

We calculate the probability that the rapidity gaps in diffractive processes survive both eikonal and enhanced rescattering. We present arguments that enhanced rescattering, which violates soft-hard factorization, is not very strong. Accounting for NLO effects, there is no reason to expect that the black disc regime is reached at the LHC. We discuss the predictions for the survival of the rapidity gaps for exclusive Higgs production at the LHC.

1 Overview of rapidity gap survival

We discuss the effect of screening corrections (that is, the rapidity gap survival factors) in diffractive processes. In particular we study the exclusive central production of Higgs bosons or another small-size heavy system, which we collectively denote by A . The process we have in mind is $pp \rightarrow p + A + p$, where the $+$ signs indicate rapidity gaps. Usually the cross sections of such processes are calculated assuming soft-hard factorization. Symbolically it can be written as

$$\sigma = |f_g \otimes \mathcal{M}_A \otimes f_g|^2 \cdot S^2, \quad (1)$$

Figure 2: (a) The ladder structure of the triple-Pomeron amplitude between diffractive eigenstates $|\phi_i\rangle, |\phi_k\rangle$ of the proton; the rapidity y spans an interval 0 to $Y = \ln s$. (b) A multi-Pomeron diagram.

triple-Pomeron coupling to the Pomeron coupling to the proton: $g_{PPP} \equiv \lambda g_N$. Its presence will allow multi-Pomeron-Pomeron absorptive effects to be included [1]. If, for the moment, we consider a Pomeron with only one component, then the opacity satisfies the evolution equation in rapidity y , at impact parameter b ,

$$\frac{d\Omega_k(y, b)}{dy} = e^{-\lambda\Omega_i(y', b)/2} e^{-\lambda\Omega_k(y, b)/2} \left(\Delta + \alpha' \frac{d^2}{d^2b} \right) \Omega_k(y, b), \quad (2)$$

where $y' = \ln s - y$. Let us explain the meanings of the three factors on the right-hand-side of (2). If only the last factor, $(\dots)\Omega_k$, is present then the evolution generates the ladder-type structure of the bare Pomeron exchange amplitude, where the Pomeron trajectory $\alpha_P = 1 + \Delta + \alpha't$. The inclusion of the preceding factor allows for rescatterings of an intermediate parton c with the “target” proton k ; Fig. 2(a) shows the simplest (single) rescattering which generates the triple-Pomeron diagram. Finally, the first factor allows for rescatterings with the beam i . In this way the absorptive effects generated by all multi-Pomeron-Pomeron diagrams are included, like the one shown in Fig. 2(b) containing, in general, $m \rightarrow n$ multi-Pomeron vertices. There is an analogous equation for the evolution of $\Omega_i(y', b)$, and the two equations may be solved iteratively.

Now, consider a Pomeron with more components a , then these equations have a matrix form in aa' space [1]. At each step of the evolution the equation includes absorptive factors of the form $e^{-\lambda\Omega^a(y, b)/2}$. By solving the equations with and without these suppression factors, we can quantify the effect of enhanced absorption. Moreover, we start the evolution from the large component P_1 , and since the evolution equations allow a transition from one component to another (corresponding to BFKL diffusion [5] in $\ln k_t$ space), we can see how the enhanced absorption will affect the distribution of high k_t in the small size component P_3 .

If we consider pure elastic eikonal rescattering, Fig. 3, then phenomenologically we can describe the bare high-energy elastic amplitude F by just one Regge pole, see Fig. 4(a). On the other hand, we know that a sizeable part of the cross section comes from diffractive dissociation. High-mass, M , diffractive dissociation is usually described by triple-Pomeron diagram, and we

$$T = \sum \overline{\left| \begin{array}{c|c|c} F & F & \dots & F \end{array} \right|} = 1 - e^{-F/2}$$

Figure 3: Pure elastic eikonal scattering.

Figure 4: (a) The bare pole amplitude; (b) the triple-Pomeron diagram describing high mass, M , diffractive dissociation; (c) the contribution of the triple-Pomeron coupling to central exclusive production.

have to include this contribution both in the irreducible amplitude F (that is, the pp opacity) as in Fig. 4(b), and in the bare amplitude for central exclusive production, as in Fig. 4(c). The latter corresponds to a contribution to the so-called enhanced screening factor S_{enh} of Fig 1. Physically, this factor accounts for the absorption of intermediate partons inside the original central exclusive amplitude. It is called *enhanced* since we have to multiply the probabilities of absorption on each individual intermediate parton, and thus the final effect is *enhanced* by the large multiplicity of intermediate partons.

A complication is that S_{enh} cannot be considered simply as an overall multiplicative factor. The probability of interaction with a given intermediate parton depends on its position in configuration space; that is, on its impact parameter $\mathbf{b}$ and its momentum k_t . This means that S_{enh} simultaneously changes the distribution of the active partons which finally participate in the hard subprocess.

We are now in a position to calculate the rapidity gap survival factors including not just *eikonal* rescattering, but also allowing for the possibility of *enhanced* screening.

2 Eikonal screening

The gap survival factor caused by *eikonal* rescattering of the Good-Walker eigenstates [6], for a fixed impact parameter $\mathbf{b}$, is

$$S_{\text{eik}}^2(\mathbf{b}) = \frac{\left| \sum_{i,k} |a_i|^2 |a_k|^2 \mathcal{M}_{ik}(\mathbf{b}) \exp(-F_{ik}(s, \mathbf{b})/2) \right|^2}{\left| \sum_{i,k} |a_i|^2 |a_k|^2 \mathcal{M}_{ik}(\mathbf{b}) \right|^2}. \quad (3)$$

The F_{ik} are the s -channel two-particle *irreducible* amplitudes for the scattering of the various diffractive eigenstates¹ $|\phi_i\rangle$ and $|\phi_k\rangle$, for given separations $\mathbf{b} = \mathbf{b}_1 - \mathbf{b}_2$ between the incoming protons

$$F_{ik}(Y, \mathbf{b}) = \frac{1}{\beta_0^2} \sum_a \int \Omega_k^a(y, \mathbf{b}_1, \mathbf{b}_2) \Omega_i^a(Y - y, \mathbf{b}_1, \mathbf{b}_2) d^2b_1 d^2b_2 \delta^{(2)}(\mathbf{b}_1 - \mathbf{b}_2 - \mathbf{b}) \quad (4)$$

where $Y = \ln s$. It is the total opacity of the ik interaction. It includes the sum over the different Pomeron components a and the integral over the impact parameter which accounts for the overlap of the partonic wave functions (that is, the opacities Ω_i and Ω_k) generated by the beam and target protons for fixed $\mathbf{b} = \mathbf{b}_1 - \mathbf{b}_2$ separation. The factor $1/\beta_0^2$ provides the appropriate normalisation as explained in the preceding paper [1].

The most topical case is Central Exclusive Diffractive (CED) production of a Higgs boson (or other heavy system of small size) [7, 8, 9, 10]. Then the matrix element $\mathcal{M}_{ik}$ of the hard subprocess $gg \rightarrow A$ can be calculated perturbatively, since the large mass and small size of the centrally produced object introduces a large scale [7, 8]. However, the shape of $\mathcal{M}_{ik}$ in impact parameter space $\mathbf{b}$ and the relative couplings of the hard matrix element to different Good-Walker eigenstates $|\phi_i\rangle$ are not known. Their calculation is beyond the ability of perturbative QCD.

One possibility is to say that the $\mathbf{b}$ dependence of $\mathcal{M}$ should be, more or less, the same as for diffractive J/ψ electroproduction ($\gamma + p \rightarrow J/\psi + p$), and the coupling to the $|\phi_i\rangle$ component of the proton should be proportional to the same factor γ_i , as in a soft interaction. This leads to

$$\mathcal{M}_{ik} \propto \gamma_i \gamma_k \exp(-b^2/4B) \quad (5)$$

with $B \simeq 4 \text{ GeV}^{-2}$ [11]. Under these assumptions, the ‘soft’ model of [1] predicts $S_{\text{eik}}^2 = 0.017$ for the LHC energy, which is close to the value 0.023 obtained recently by the Tel-Aviv group [12].

¹Recall that, in the global model of soft interactions of the preceding paper [1], the Good-Walker formalism [6] was used to decompose the proton wave function in terms of three diffractive eigenstates $|p\rangle = \sum_i a_i |\phi_i\rangle$. That is, we used a three-channel eikonal to describe elastic rescattering and low-mass proton dissociation.

Figure 5: (a): A symbolic representation of (6); (b) and (c): diagrams relevant for the computation of S_{enh}^2 and $S_{\text{eik}}^2 S_{\text{enh}}^2$ of (8) and (9), where $\underline{\Omega}$ is the opacity when the screening corrections embracing the hard matrix element are neglected.

Expressing the survival factors in this manner is too simplistic. However, these numbers are frequently used as the reference point. This can be misleading, since S^2 calculated in this way strongly depends on an additional assumption about the slope B , a quantity which is mainly of ‘soft’ origin.

Another, more plausible and self-consistent, possibility is to calculate $\mathcal{M}_{ik}(\mathbf{b})$ under the assumption that the active gluons that participate in the hard subprocess come from the small-size component P_3 of the Pomeron. That is,

$$\mathcal{M}_{ik}^{\text{enh}}(\mathbf{b}) = \frac{M(gg \rightarrow A)}{\beta_0^2} \int \Omega_i^{P_3}(y_1, \mathbf{b}_1, \mathbf{b}_2) \Omega_k^{P_3}(y_2, \mathbf{b}_1, \mathbf{b}_2) d^2 b_1 d^2 b_2 \delta^{(2)}(\mathbf{b}_1 - \mathbf{b}_2 - \mathbf{b}), \quad (6)$$

where the rapidities $y_j = -\ln \xi_j$ with $j = 1, 2$, correspond to the momentum fractions carried by the active gluons which participate in the hard subprocess with matrix element $M(gg \rightarrow A)$. The superscript “enh” is to indicate that the matrix element calculated in this way already accounts for the “enhanced” rescattering on intermediate partons. A symbolic representation of the formula is given in Fig. 5(a). The formula is similar to formula (4) for the irreducible amplitude $F_{ik}(\mathbf{b})$. The difference is that now the two active gluons are separated by a large rapidity interval $\ln M_A^2$, so that $y_1 + y_2 = Y - \ln M_A^2$.

3 Enhanced screening

However, as mentioned above, besides pure eikonal screening, there may be *enhanced* rescattering arising from absorption of the intermediate partons in the hard matrix element $\mathcal{M}_{ik}$.

Working at LO (of collinear approximation) we have to neglect such an effect. Due to strong k_t -ordering the transverse momenta of all the intermediate partons are very large (i.e. the transverse size of the Pomeron is very small) and therefore the absorptive effects are negligible. Nevertheless, this may be not true at a very low x , where the parton densities become close to saturation and the small value of the absorptive cross section is compensated by the large value of the parton density.

Indeed, the contribution of the first *enhanced* diagram, which describes the absorption of an intermediate parton, was estimated in the framework of the perturbative QCD in Ref.[13]. It turns out that it could be quite large. On the other hand, such an effect is not seen experimentally. The absorptive corrections due to enhanced screening must increase with energy. This is not observed in the present data (see [3] for a more detail discussion). One reason is that the gap survival factor S_{eik}^2 already absorbs almost all the contribution from the centre of the disk. The parton essentially only survives eikonal rescattering on the periphery, that is at large impact parameters b . On the other hand, on the periphery, the parton density is rather small and the probability of *enhanced* absorption is not large. This fact can be seen in Ref. [14]. There the momentum, Q_s , below which we may approach saturation, was extracted from the HERA data in the framework of the dipole model. Already at $b = 0.6$ fm the value of $Q_s^2 < 0.3$ GeV² for the relevant $x \sim 10^{-6}$.

Recall that, in our model, the absorption caused by rescattering of intermediate partons is included as exponential factors, $e^{-\lambda(\Omega_i + \Omega_k)/2}$, in equations (2) for the opacities. So we have the possibility to quantify the role of this (‘enhanced’) exponential suppression by solving the evolution equations with and without the exponential factors.

First, we could calculate the value of $\mathcal{M}_{ik}$ *excluding* any effect of ‘enhanced’ absorption. To do this we would delete the factors $e^{-\lambda(\Omega_k + \Omega_i)/2}$ from the equation (2), and then solve the modified equations for opacities Ω_i and Ω_k respectively. However, this is not what we need, and before we start the calculation it is necessary to note two pragmatic observations. The problem is that we no longer have exact factorisation between the hard and soft parts of the process. Thus before computing the effect of soft absorption we must fix what is included in the bare CED amplitude calculated in terms of perturbative QCD.

4 Matching S^2 with the hard matrix element

The first observation is that the bare amplitude is calculated as a convolution of two generalised (skewed) gluon distributions with the hard subprocess matrix element [7, 8]. These gluon distributions are determined from integrated gluon distributions of a global parton analysis of mainly deep inelastic scattering data. However, these phenomenological integrated parton distributions already include the interactions of the intermediate partons with the parent proton. As a consequence, in order to determine S_{enh}^2 we should compare the matrix element calculated including all enhanced diagrams, like the one sketched in Fig. 5(a), with the matrix element

obtained by excluding, in the evolution of Ω_i , the exponential factor $e^{-\lambda\Omega_k/2}$ which ‘embraces’ the hard subprocess, and keep only $e^{-\lambda\Omega_i/2}$, as indicated in Fig. 5(b); and vice versa for the evolution of Ω_k . In this way we mimic the gluons used in the perturbative QCD calculation of the cross section. Let us denote the opacities, obtained this way, as $\underline{\Omega}$ and the corresponding matrix element of (6) as $\underline{\mathcal{M}}_{ik}(\mathbf{b})$. These opacities mimic the phenomenological gluon distributions used in the perturbative QCD calculation. So, for fixed indices i, k , the enhanced survival factor is given by

$$S_{\text{enh}}^2 = \frac{|\mathcal{M}^{\text{enh}}|^2}{|\underline{\mathcal{M}}|^2}. \quad (7)$$

Now we are ready to calculate the survival factors. We would like to compare the survival factors computed as indicated in Fig. 5(b) and (c). First, corresponding to Fig. 5(c), we compute $S_{\text{eik}}^2(\mathbf{b})$ from (3) where $\mathcal{M}_{ik}^{\text{enh}}(\mathbf{b})$ includes the full enhanced screening, but not the eikonal rescattering. Symbolically we have

$$S_{\text{eik}}^2(\mathbf{b}) = \frac{|\mathcal{M}^{\text{enh}} * e^{-F_{ik}/2}|^2}{|\mathcal{M}^{\text{enh}}|^2}, \quad (8)$$

where $\mathcal{M}^{\text{enh}}$ is given by (6). Then we compute the *total* absorptive effect $S_{\text{enh}}^2(\mathbf{b}) S_{\text{eik}}^2(\mathbf{b})$ by replacing $\mathcal{M}^{\text{enh}}$ in the denominator by $\underline{\mathcal{M}}$. The calculation of $\underline{\mathcal{M}}$ corresponds to Fig. 5(b). That is,

$$S_{\text{tot}}^2(\mathbf{b}) \equiv S_{\text{enh}}^2(\mathbf{b}) S_{\text{eik}}^2(\mathbf{b}) = \frac{|\mathcal{M}^{\text{enh}} * e^{-F_{ik}/2}|^2}{|\underline{\mathcal{M}}|^2}. \quad (9)$$

The second observation is that the phenomenologically determined generalised gluon distributions are usually taken at $p_t = 0$, and then the observed “total” cross section is calculated by integrating over p_t of the recoil protons *assuming* an exponential behaviour $e^{-Bp_t^2}$; that is

$$\sigma = \int \frac{d\sigma}{dp_{1t}^2 dp_{2t}^2} dp_{1t}^2 dp_{2t}^2 = \frac{1}{B^2} \left. \frac{d\sigma}{dp_{1t}^2 dp_{2t}^2} \right|_{p_{1t}=p_{2t}=0}, \quad (10)$$

where

$$\int dp_t^2 e^{-Bp_t^2} = 1/B = \langle p_t^2 \rangle. \quad (11)$$

However, the total soft absorptive effect changes the p_t distribution in comparison to that for the bare cross section determined from perturbative QCD. Moreover, the correct p_t dependence of matrix element (6) does *not* have an exponential form. Thus the additional factor introduced by the soft interactions is not just the gap survival S^2 , but rather $S^2 \langle p_t^2 \rangle^2$, where the square arises since we have to integrate over the p_t distributions of *two* outgoing protons. Indeed in all the previous calculations the soft prefactor had the form² S^2/B^2 . Now, in our model the

²At larger impact parameter b the absorption is weaker. Hence the value of S^2 increases with the slope B . It was shown that the ratio S^2/B^2 is approximately stable for reasonable variations of B [15].

Figure 6: The survival factors for the Central Exclusive Diffractive (CED) production of a heavy 0^+ system of mass $M_A=150$ GeV and $M_A=10$ GeV.

$\mathbf{b}$ behaviour of $\mathcal{M}(\mathbf{b})$ is driven by the opacities. Thus we present the final result in the form $S^2 \langle p_t^2 \rangle^2$, and so to compare it with previous predictions obtained for $B = 4 \text{ GeV}^{-2}$ we need to introduce the “renormalisation” factor $(\langle p_t^2 \rangle B)^2$. The resulting (effective) value is denoted by S_{eff}^2 .

5 Impact parameter dependence of S_{enh}^2

First, we present the results of the calculation of the survival factors at fixed pp impact parameter $\mathbf{b} = \mathbf{b}_1 - \mathbf{b}_2$; that is, before integrating over d^2b . The results are presented in Fig. 6 for the LHC energy $\sqrt{s} = 14$ TeV for, first, the production of a Higgs boson of mass $M_A = 120$ GeV and, second, for the central production of an object of mass $M_A = 10$ GeV (which may be a pair of high- E_T photons or a χ_b). For the 10 GeV object we assume that the active gluons come from the intermediate Pomeron state, P_2 . As expected the eikonal suppression, S_{eik}^2 , is almost the same for both objects (with a bit stronger suppression for P_3 which lies in a bit smaller $\mathbf{b}$ domain). On the other hand, the enhanced suppression, S_{enh}^2 , is stronger for the lighter object as the rapidity interval allowed for the interaction with the intermediate partons is considerably larger, and the absorption cross section is larger for a lower k_t parton.

After we multiply the bare QCD amplitude, shown by the dashed line in the plots of Fig. 6, by the total survival factors we obtain the impact parameter profiles of the final CED signal which peak around 0.8 fm. The signal vanishes as $b \rightarrow 0$ simply because we plot the integrand

$b|\mathcal{M}|^2$ of $\int d^2b S^2|\mathcal{M}(\mathbf{b})|^2 = 2\pi \int b|\mathcal{M}(\mathbf{b})|^2 db$; the normalisation of the signal in the figure was chosen to facilitate the plot.

Assuming that all the partons are distributed homogeneously, we would expect $S_{\text{enh}}^2 \rightarrow 1$ at the large values of b of the periphery. However, the results show only a weak tendency to increase at large b . Thus, in the ‘soft’ model of [1] (with a small value of α'_P), S_{enh}^2 comes mainly from “hot-spots” in which many individual intermediate partons are concentrated within small b domains. In other words, most of enhanced absorption occurs within the same parton shower, and is due to secondaries produced during the evolution with the same impact parameter b . On the other hand, a detailed analysis [14] of HERA data shows that the value of the saturation scale $Q_s(b)$ decreases rapidly with increasing b . (Q_s is the inverse size of the dipole for which absorptive corrections become important.) This indicates that parton-parton correlations are too strong in the present model. Therefore we consider our results are close to the maximum possible gap suppression.

6 Possible role of NLO effects

6.1 Threshold factors

The evolution equation for Ω_k^a , (2), and the analogous one for Ω_i^a , are written in the leading $\ln(1/x)$ approximation, without any rapidity threshold. The emitted parton, and correspondingly the next rescattering, is allowed to occur just after the previous step. On the other hand, it is known that a pure kinematical t_{min} effect suppresses the probability to produce two partons close to each other. Moreover, this t_{min} effect becomes especially important near the production vertex of the heavy object. It is therefore reasonable to introduce some threshold rapidity gap, Δy and to compute S_{enh}^2 only allowing for absorption outside this threshold interval. The results of Fig. 6 were calculated for $\Delta y = 1.5$. The same rapidity interval was used to separate low- and high-mass diffractive dissociation in the model [1]. Below, we present the results for the survival factors for $\Delta y = 0, 1.5, 2.3$. For $\Delta y = 2.3$ all the NLL BFKL corrections [16] may be reproduced by the threshold effect [2, 3, 4, 17]. Technically we can allow for a non-zero Δy by just shifting y_j to $y_j = \ln 1/\xi_j - \Delta y$.

For the CED production of a high E_T photon pair at the Tevatron with the “threshold” $\Delta y = 2.3$ ($\Delta y = 0$) we reproduce only one half (1/7) of the value of the full gap survival factor $S_{\text{eff}}^2 = 0.05$ that was used in [18] to predict the corresponding cross section. For lighter CED χ_c production, where the ‘enhanced’ absorption is stronger (that is S_{enh} is smaller) with $\Delta y = 2.3$ we now obtain³ about factor 0.35 smaller prediction than that published in [15]. For the CED Higgs boson production at the LHC, the model gives $S_{\text{eff}}^2 = 0.004, 0.09$ and 0.015 for $\Delta y = 0, 1.5$ and 2.3 respectively.

³We assume that the non-perturbative contribution is caused by the largest-size Pomeron component P_1 , while the perturbative contribution is due to the second component P_2 .

The existing data from the Tevatron for exclusive $\gamma\gamma$ [19], dijet [20] and χ_c [21] production are in agreement with the predictions [18, 15], indicating that actually the value of $\langle S_{\text{enh}}^2 \rangle$ is larger than obtained by the ‘soft’ model of [1]. So, we should regard

$$\langle S_{\text{eff}}^2 \rangle = 0.015 \pm 0.01 \quad (12)$$

as a conservative (lower) limit for the gap survival probability in the exclusive production of a Higgs boson of mass 120 GeV at the LHC. Recall that this effective value should be compared with S^2 obtained using the exponential slope $B = 4 \text{ GeV}^{-2}$.

6.2 Black Disc Regime (BDR)

Note that, at relatively low scales, $Q^2 \lesssim 3 \text{ GeV}^2$, the NLO gluon density extracted from the global parton analyses [22] does not increase with $1/x$. Since the absorptive cross section $\sigma_{\text{abs}} \sim \alpha_s/Q^2$ decreases with increasing Q^2 faster than the gluon density grows ($xg \sim (Q^2)^\gamma$ with $\gamma < 0.5$), the role of larger scales is even smaller. Given this phenomenological observation, we may assume that, for $\sqrt{s} > 1 \text{ TeV}$, the parton density which controls the ‘enhanced’ absorptive effect, does not grow with increasing energy. Hence the S_{enh}^2 factor will depend *only* on the available rapidity interval for enhanced rescattering; that is, on the M_A^2/s ratio. but *not* on the initial energy.

This observation clearly contradicts the assumption that the black disc regime (BDR) will have been reached at the LHC energy [23]; and that the low x gluon density will be so large that only on the far periphery of the proton, $b > 1 \text{ fm}$, will there be a chance to avoid an additional inelastic interaction, so that the gap survives.

Recall that the BDR of [23] was obtained using *leading order* (LO) gluons which grow steeply with $1/x$. This growth is simply an artefact of the absence of a LO coefficient function, $C_{\gamma g}^{(0)} = 0$, corresponding to γg fusion in deep inelastic scattering (DIS), and that there is *no* $1/z$ singularity in the LO quark-quark splitting function, $P_{qq}(z)$. In order to reproduce the DIS data, these deficiencies are compensated by an artificially large gluon density at low x values⁴. When the NLO (and NNLO) contributions are included the DIS data are described by a flat (or even decreasing with $1/x$) gluon at the relevant moderately low scales. With such a flat distribution, we expect that the value of S_{enh}^2 for central exclusive Higgs production at the LHC will be *larger* than that for the exclusive production of a pair of high E_T photons at the Tevatron

$$S_{\text{enh}}^{\text{LHC}}(M_H > 120 \text{ GeV}) > S_{\text{enh}}^{\text{Tevatron}}(\gamma\gamma; E_T > 5 \text{ GeV}) > S_{\text{enh}}^{\text{Tevatron}}(\chi_c). \quad (13)$$

Actually, in the preceding model of soft interactions [1], the parton density grows slowly with energy. After the absorptive factors $e^{-\lambda\Omega/2}$ are included in the evolution (2), the power

⁴We thank Robert Thorne for discussions.

growth of the opacity $\Omega \sim s^\Delta$ is replaced by the logarithmic asymptotic behaviour $\Omega \sim \ln \ln s$ [24]. As a result, instead of a strong BDR suppression, the value of $\langle S_{\text{enh}}^2 \rangle$ decreases by only 20-30% when going from the Tevatron to the LHC energy, keeping the ratio $M_A/\sqrt{s} = 0.01$ fixed.

In our model we do not specify the nature of the soft partons. However, when we introduce BFKL we imply the partons are gluons, and so the screening exponents were chosen assuming gluons in both Pomerons. In terms of QCD, at small x and low scales, the increase of the parton density with decreasing x found in our model may reflect the growth of the NLO sea quark density⁵ with decreasing x . This growth is less steep than that of the LO gluons, but is not negligible.

Note that the central exclusive amplitudes of interest are driven by gluon-gluon fusion: for example, $gg \rightarrow H$, $gg \rightarrow \gamma\gamma$ and $gg \rightarrow \chi_c$. If, as noted above, there is a screening (NLO) sea-quark contribution in these amplitudes, then the effective colour factor is smaller.

So, actually, in Nature, we expect a *larger* value of S_{enh} . First, because of the colour-factor suppression when the gluons are screened by quarks, which was not included in [1]. Secondly, due to a much stronger ‘hot-spot’ parton-parton correlation in b -space in the model of [1] than that indicated by the HERA data.

7 Comparison with exclusive Tevatron data

This conclusion is confirmed by the CDF exclusive data obtained at the Tevatron. The recent observations of central exclusive $\gamma\gamma$ [19], dijet [20] and χ_c [21] production are in overall agreement with the old KMR predictions based on the global soft model of 2000 [9]. In detail, the data exceed the predictions [18] for $\gamma\gamma$ production, although here the present event rate is very low; whereas the predictions [15], based on the KMR2000 model, are a bit above the observed χ_c production.

How does the present soft model [1], which includes enhanced rescattering effects change the predictions? Clearly, the overall gap survival probability S^2 will be smaller than that based on KMR2000. However, the difference is not large for the exclusive production, $pp \rightarrow p + A + p$, of a heavy system A . To be precise, for $M_A = 120$ GeV, the ‘old’ soft survival prefactors are⁶

$$\langle S^2 \rangle \langle p_t^2 \rangle^2 = 0.0015 \quad \text{at the LHC} \quad (\text{KMR2000})$$

$$\langle S^2 \rangle \langle p_t^2 \rangle^2 = 0.0030 \quad \text{at the Tevatron,}$$

while the present soft model [1], which includes enhanced rescattering, gives

$$\langle S^2 \rangle \langle p_t^2 \rangle^2 = 0.0010 \quad \text{at the LHC} \quad (\text{KMR2008})$$

⁵At NLO the gluon density in this domain is approximately flat in x .

⁶The results, based on KMR2000 [9], in the form $\langle S^2 \rangle \langle p_t^2 \rangle^2$ were published in [15].

$$\langle S^2 \rangle \langle p_t^2 \rangle^2 = 0.0025 \text{ at the Tevatron,}$$

where all these numbers have units of $(\text{GeV})^4$. We see that the inclusion of enhanced rescattering does reduce the exclusive $pp \rightarrow p + A + p$ cross section, but well within the uncertainty. However, for the relatively light χ_c the available rapidity interval for the enhanced suppression is large. In this case we find that the inclusion of enhanced rescattering causes a larger difference – reducing the exclusive cross section by about $\frac{1}{3}$. As a result, the new ‘prediction’, which includes S_{enh} , is a bit below the CDF data on central exclusive χ_c production [21], rather than a bit above as for our old prediction [15] based on KMR2000 [9].

Recall that there is no theoretical or phenomenological reason to have a strong energy dependence of the gap survival factor S^2 . So the CDF central exclusive data measured at the Tevatron can be used to check and to confirm the central exclusive cross sections predicted at the LHC. Forthcoming higher-statistics data from the Tevatron will be valuable to further check our predictions for exclusive processes at the LHC.

8 Summary

We briefly list the main findings of our analysis.

- Enhanced rescattering of intermediate partons occurring in an exclusive amplitude is not negligible. It violates soft-hard factorization, modifying the input parton distributions used in the QCD calculation of the bare $pp \rightarrow p + A + p$ amplitude, in comparison with those measured in deep inelastic scattering.
- However, the suppression caused by S_{enh}^2 is numerically not large for the exclusive production of a heavy mass system (like a Higgs boson) at the LHC.
- We noted two results of NLO analyses of HERA data. First, ‘flat’ small- x gluons are obtained at the relevant scales in the global fits of deep inelastic and related data. Second, small values of the saturation scale $Q_s(b)$ are obtained for impact parameters larger than about 0.6 fm. These observations imply that the gluon density, which gives rise to the enhanced absorptive correction, is not large, and that the black disc regime is not reached at the LHC.
- The energy dependence of the gap survival factor is smooth. Therefore exclusive $p\bar{p} \rightarrow p + A + \bar{p}$ data observed at the Tevatron can be used to evaluate the suppression expected at the LHC.
- The present Tevatron data imply that the predictions given here (and in related papers) should be considered as conservative lower limits. This offers the possibility for the observation of Higgs bosons in exclusive processes at the LHC.

Acknowledgements

We thank Mike Albrow, Aliosha Kaidalov, Risto Orava, Andy Pilkington and Robert Thorne for useful discussions. MGR thanks the IPPP at the University of Durham for hospitality. The work was supported by grant RFBR 07-02-00023, by the Russian State grant RSGSS-3628.2008.2.
